

PERMIAN-TRIASSIC (260-220 MA) CRUSTAL GROWTH OF EASTERN CENTRAL ASIAN OROGENIC BELT AS REVEALED BY DETRITAL ZIRCON STUDIES

FANXUE MENG^{*,**,*†}, SHAN GAO^{*,**,*†}, HONGLIN YUAN^{***},
and HUJUN GONG^{***}

ABSTRACT. Present global compilations of ages and isotopic data suggest insignificant crustal growth after 450 Ma. Previous Nd isotopic studies of whole rocks from the Central Asian Orogenic Belt suggest large volumes of juvenile crustal additions in the Phanerozoic. To test this, we studied detrital zircons from the Xinglonggou Formation of western Liaoning at the northern margin of the North China craton, which was deposited after the collision between the Siberian Plate and the North China craton to form this part of the Central Asian Orogenic Belt. Zircons from the Xinglonggou sandstones are characterized by two major groups of U-Pb ages (2.6-2.4 Ga and 260-220 Ma) except for three grains (1.9-1.6 Ga). The 2.6 to 2.4 Ga zircons have positive $\epsilon_{\text{Hf}}(t)$ values up to coeval depleted mantle value, which suggest juvenile crustal addition. The results are consistent with existing data for the North China craton (NCC). $\epsilon_{\text{Hf}}(t)$ values of 260 to 220 Ma zircons range widely from -15.4 to 13.3 . While zircons with the negative $\epsilon_{\text{Hf}}(t)$ values are similar to igneous zircons from intrusive rocks of the North China craton and indicate recycling of ancient continental crustal materials, those with the positive values and young model ages point to a significant period of crustal generation with the source provenance from the eastern Central Asian Orogenic Belt (CAOB) to the north. Mixing of detritus from both the North China craton and the eastern Central Asian Orogenic Belt suggests the ca. 250 Ma closure of the Paleo-Asian ocean and collision between the North China craton and the Siberian Plate along the eastern Solonker zone. The youngest zircons constrain uplift of the eastern Central Asian Orogenic Belt to be no older than 208 Ma. Thus, the 260 to 220 Ma crustal growth is related to the subduction of the Paleo-Asian ocean Plate along the Solonker suture, which records the termination of the Central Asian Orogenic Belt. The Solonker suture occupies an area of 700 km long and 60 km wide and extends from Solonker via Sonid Yuoqi to Linxi in Inner Mongolia and further west and northeast. This implies extensive juvenile crustal additions during this period. It may change our present views of Phanerozoic crustal growth.

Key words: Detrital zircon, U-Pb age, Hf isotope, North China craton, Crustal growth.

INTRODUCTION

Clastic sediments and sedimentary rocks are ideal samples for studying formation, evolution, and chemical composition of the continental crust (for example, Goldschmidt, 1933; Taylor and others, 1983; Taylor and McLennan, 1985; McLennan, 2001; Rudnick and Gao, 2003; Kemp and others, 2006; Hu and Gao, 2008; Hawkesworth and others, 2010). Detrital zircon is providing the most valuable information for this purpose, because its robust chemical and physical properties allows it to survive later disturbances and different growth zones within zircon crystals can be dated by U-Pb

isotopes, while their trace elements and Lu-Hf and O isotopic compositions provide an exceptional record of magmatic, and thus continental crustal evolution (Griffin and others, 2004; Condie and others, 2005, 2009; Iizuka and others, 2005; Veevers and others, 2005; Hawkesworth and Kemp, 2006a, 2006b; Coogan and Hinton, 2006; Kemp and others, 2006; Weislogel and others, 2006; Campbell and Allen, 2008; Yang and others, 2009; Hawkesworth and others, 2010). The zircon thermometer adds additional important information on the formation and evolution of the continental crust (Watson and Harrison, 2005; Watson and others, 2006; Ferry and Watson, 2007).

It has been estimated that >50 percent volume of the present continental crust formed by 2.5 Ga and >90 percent by 540 Ma (Taylor and McLennan, 1995; Hawkesworth and Kemp, 2006a). Worldwide compilations of zircon ages from juvenile crust indicate striking age peaks around 2.7 Ga, 1.9 Ga and 1.2 Ga, which suggest episodic rapid continental growth during thermal pulses associated with emplacement of mantle plumes (Condie, 1998, 2000). Post 1.2 Ga zircons show no such significant age peaks. Recent compilations of zircon ages of worldwide granitoids reveal seven igneous age peaks (3300, 2700, 2680, 2500, 2100, 1900 and 1100 Ma) (Condie and others, 2009). Nd isotope distributions of granitoids suggest important additions of juvenile continental crust at 2700, 2500, 2120, 1900, 1700, 1650, 800, 570 and 450 Ma (Condie and others, 2009). These compilations do not suggest significant crustal growth after 450 Ma.

There are cases of classic orogenic belts (Caledonides, Hercynides, Canadian Cordillera, Lachlan and New England Foldbelts, Central Asian Orogenic belts) where Phanerozoic crustal growth is considered to be significant based on positive $\epsilon_{Nd}(t)$ of granitoids (Jahn and others, 2000a, 2000b; Wu and others, 2000). However, *in-situ* determinations of U-Pb ages, Hf and oxygen isotopes of detrital zircons from the Lachlan Fold Belt of southeastern Australia reveal two prominent linear arrays that intersect the depleted mantle growth curve near 1.9 and 3.3 Ga ago (Kemp and others, 2006). The data indicate that crustal generation in part of Gondwana was limited to major pulses at 1.9 and 3.3 Ga, and the Phanerozoic zircons crystallized during repeated reworking of crust formed at these times. These results highlight the importance of *in-situ* zircon isotopic studies compared to whole-rock analysis, which may be compromised by mixing processes.

The Central Asian Orogenic Belt (CAOB) occupies a vast area that extends >5000 km from west to east and 1000 to 2000 km wide situated between the Siberian craton and North China. Previous Nd isotopic studies of whole rocks from the Central Asian Orogenic Belt suggest significant juvenile crustal additions in the Phanerozoic (500-120 Ma) (for example, Zonenshain and others, 1990; Sengör and others, 1993; Sengör and Natal'in, 1996; Jahn and others, 2000a, 2000b; 2004; Windley and others, 2007). The crustal growth was thought to be related to subduction-accretion with punctuated collision events between accreted blocks (Mossakovsky and others, 1994; Wu and others, 2000; Buchan and others, 2001; Hong and others, 2004; Helo and others, 2006; Jian and others, 2008). To test the large volume of Phanerozoic crustal growth in the Central Asian Orogenic Belt, we analyzed U-Pb ages and Hf isotopic compositions of detrital zircons from the Xinglonggou Formation in western Liaoning, which is located in the northern part of the North China craton (NCC). The North China craton collided with the Siberian Plate along the Central Asian Orogenic Belt. The Xinglonggou sandstones were deposited after the collision and thus provide clues to the sources of the Central Asian Orogenic Belt and the North China craton.

GEOLOGICAL SETTINGS AND SAMPLES

The Central Asian Orogenic Belt extends from the Urals Mts. via Kazakhstan, Kyrgyzstan, northwestern China, Mongolia and southern Siberia to the Okhotsk Sea in

the Russian Far East (Zonenshain and others, 1990; Sengör and others, 1993; Mossakovsky and others, 1994; Yakubchuk and others, 2001; Yakubchuk, 2002). It is sandwiched between the Siberian craton in the north and the North China and Tarim cratons in the south (fig. 1A). It is composed of a variety of tectonic units, including Precambrian micro-continental blocks, ancient island arcs, ocean islands, accretionary complexes, ophiolites and passive continental margins. The amalgamation of these terranes occurred at various times in the Paleozoic and Mesozoic and was accompanied by episodes of magmatism, ranging in age from Ordovician (ca. 450 Ma) to Triassic-Cretaceous (ca. 220-120 Ma) that resulted in the emplacement of large volumes of granitoid intrusions (Jahn, 2004) and mafic volcanic rocks (Zhu and others, 2005), accompanied by lesser volumes of mafic-ultramafic rocks (Pirajno and others, 2008). Its growth began at ca. 1.0 Ga (Khain and others, 2002) and continued to ca. 250 Ma, when the Paleo-Asian ocean closed (Xiao and others, 2003).

The Solonker zone (fig. 1B) has been widely regarded as the site of final closure of the Paleo-Asian ocean (Tang, 1990; Sengör and others, 1993; Xiao and others, 2003; Wu and others, 2007; Chen and others, 2009). However, there is still much controversy concerning the timing of suturing. Some workers proposed that suturing took place during the Permian to early Triassic (300-230 Ma) (Sengör and others, 1993; Chen and others, 2000, 2009; Xiao and others, 2003; Wu and others, 2007; Jian and others, 2010); some preferred suturing during either the middle Devonian (Tang, 1990) or late Devonian to early Carboniferous (400-320 Ma) (Shao, 1991; Hong and others, 1995; Xu and Chen, 1997); others advocated a middle Mesozoic (130-110 Ma) suturing based on a controversial amphibolite $^{40}\text{Ar}/^{39}\text{Ar}$ age (Nozaka and Liu, 2002). The southern accretionary zone between the North China craton and the Solonker suture is characterized by the Mid-Ordovician-Early Silurian (ca. 488-438 Ma) (Jian and others, 2008) Ulan island arc-Ondor Sum subduction-accretion complex and the Bainaimiao arc (fig. 1B). This zone was consolidated by the Carboniferous-Permian when it evolved into an Andean-type magmatic margin above a south dipping subduction zone. The northern accretionary zone north of the Solonker suture extends southward from a Devonian to Carboniferous active continental margin, through the Hegenshan ophiolite arc accretionary complex to the Late Carboniferous (~310 Ma) (Chen and others, 2009) Baolidao arc associated with some accreted Precambrian blocks. This northern zone had consolidated by the Permian when it developed into an Andean-type magmatic margin above a north dipping subduction zone. Final subduction of the Paleo-Asian ocean caused the two opposing active continental margins to collide, leading to formation of the Solonker suture in the end-Permian (ca. 250 Ma) (Xiao and others, 2003).

The Central Asian Orogenic Belt is celebrated for its massive juvenile crustal production in the Phanerozoic (for example, Jahn and others, 2000a, 2000b). This is evidenced by the emplacement of voluminous granitoids of 500 to 120 Ma in age with low initial Sr isotopic ratios, generally positive $\epsilon_{\text{Nd}}(t)$ values and young Nd model ages (Shao and others, 1999; Chen and others, 2000; Jahn and others, 2000a, 2000b; Wu and others, 2000, 2002, 2003b, 2007). It should be noted that all these studies are based on whole-rock data, which may be compromised by mixing processes. For example, the whole rock Nd model ages range from 1028 to 645 Ma with an average of 764 Ma (Wu and others, 2003b), which are remarkably older than the age of magma and imply mixing with older crust if the Phanerozoic magma represented juvenile additions from the mantle. However, this is unclear. Two gigantic magmatic belts can be recognized in the Central Asian Orogenic Belt: a northern belt from central-northern Mongolia to Russian Transbaikalia and a southern belt from Kazakhstan through northern Xinjiang (NW China), southern Mongolia, to northeastern China (Chen and Arakawa, 2005).

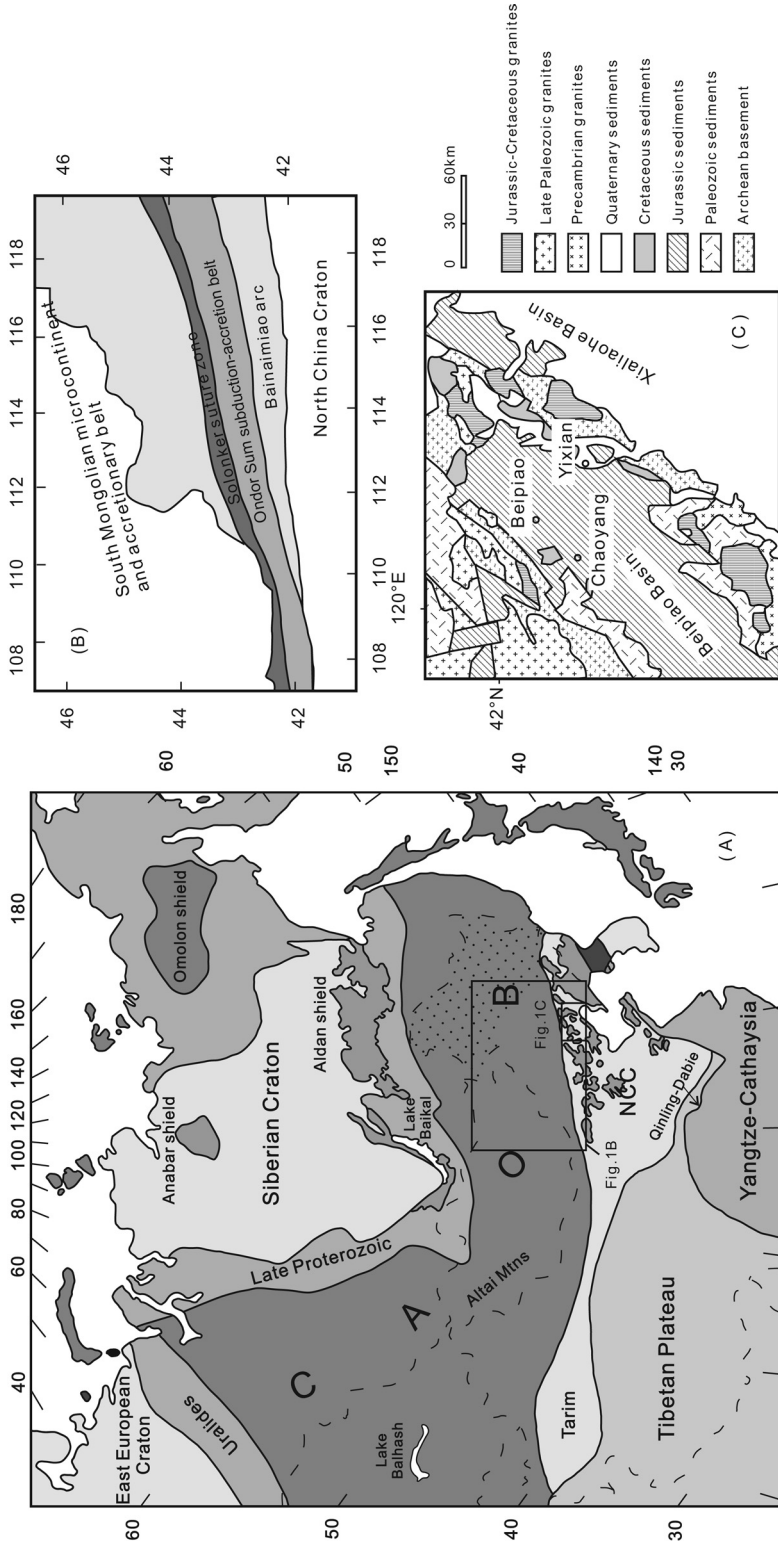

Fig. 1. (A) Simplified tectonic divisions of Central Asian Orogenic Belt (CAOB) (after Kröner and others, 2008), which is situated between the Siberian craton in the north and the North China (NCC) and Tarim cratons in the south. The dot area indicates drainage basins of rivers sampled for detrital zircon studies (Li, ms, 2010); (B) sketch map of Solonker suture zone (after Chen and others, 2009); (C) geologic map of western Liaoning Province (after Yan and others, 2006).

Previous studies of ophiolites and post-collision intrusive rocks suggest a west-east younging trend of a scissor-like closure of the Mongol-Okhotsk ocean (Donskaya and others, 2008). This is also true for the southern belt. In the western Central Asian Orogenic Belt (including Altai, Tianshan, and Kazakhstan), the closure occurred in the Late Carboniferous according to the ages of ophiolites and arc lavas (for example, Xu and others, 2006; Kröner and others, 2008), while the post-collision intrusive rocks mainly produced at 300 to 280 Ma, indicating a post-collisional environment in the Permian (for example, Han and others, 1997; Chen and Jahn, 2004; Wang and others, 2005, 2009). For example, in northern Xinjiang, post-collision granites were emplaced at about 340 to 265 Ma (Chen and Jahn, 2004; Chen and Arakawa, 2005; Wang and others, 2005; Han and others, 2006; Liu and Pan, 2006; Tong and others, 2006; Konopelko and others, 2007; Zhao and others, 2008; Zhou and others, 2008). However, the final closure of the Paleo-Asian ocean in the eastern Central Asian Orogenic Belt (including Inner Mongolia and northeastern China) occurred in the Permian-Triassic (296-230 Ma), which produced the Solonker suture (Sengör and others, 1993; Chen and others, 2009; Xiao and others, 2003). The ophiolites were dated at 299 to 284 Ma (Jian and others, 2008, 2010). Post-orogenic granitic rocks in Inner Mongolia were emplaced at ca. 280 Ma (Shi and others, 2004; Wang and others, 2004). In northeastern China, the existing age data indicate Phanerozoic granitic emplacement took place mainly from the Late Paleozoic to Late Mesozoic, which focused on Late Permian (270-250 Ma), Late Triassic-Early Jurassic (230-180 Ma), Middle Jurassic (170-150 Ma) and Cretaceous (ca. 120 Ma) (Chen and others, 2000; Jahn and others, 2000a, 2000b, 2001, 2004; Fan and others, 2003; Shi and others, 2004; Wu and others, 2000, 2002, 2003a, 2004, 2007; Ge and others, 2005; Cheng and others, 2006). However, the ca. 120 Ma granites may be related to the subduction of the Pacific Plate.

The mechanisms of continental crustal growth in the Central Asian Orogenic Belt remain the subject of debate. Sengör and others (1993) suggested that the Central Asian Orogenic Belt grew by 5.3 million square kilometers during the Palaeozoic, with nearly half of this growth being derived from the mantle by subduction accretion and arc collision. This model is supported by the presence of ophiolites with ages ranging from Neoproterozoic to late Paleozoic (for example, Coleman, 1989; Gao and Klemd, 2003; Xiao and others, 2003; Liu and Pan, 2006) and occurrences of Paleozoic arc-type magmatic rocks (for example, Chen and others, 2000; Heinhorst and others, 2000; Hu and others, 2000). Conversely, many researchers argue that massive Phanerozoic Central Asian Orogenic Belt granitoids with positive ϵ_{Nd} values are A-type granites generated by extensive basalt underplating in a post-orogenic or an intraplate extensional setting (for example, Zhao and others, 1996; Han and others, 1997; Jahn and others, 2000a, 2000b; Liu, 2002; Wu and others, 2000, 2002; Liu and Pan, 2006). It is also proposed that Late Paleozoic (~330 Ma) plume activity provided the heat required to generate the large amounts of granites and associated volcanic rocks in the Central Asian Orogenic Belt (Xia and others, 2004; Zhou and others, 2004).

The Yixian-Beipiao Basin of western Liaoning is located along the northern margin of the North China craton (fig. 1C). It is bounded by the eastern Central Asian Orogenic Belt to the north. Four major periods of volcanism have been identified in western Liaoning: the Jurassic Xinglonggou and Lanqi Formations, the Early Cretaceous Yixian Formation, and the late Early Cretaceous Zhanglaogongtun Formation (Yang and Li, 2008). The Xinglonggou Formation in this area represents the first sedimentation after the final collision of the eastern Central Asian Orogenic Belt with the North China craton. This formation is exposed in the Chaoyang-Beipiao area

(fig. 1C) and variably overlies the Proterozoic Changcheng Group, the Middle Triassic strata or the Upper Triassic Laohugou Formation, and is overlain by the Beipiao Formation (Liu, *ms*, 2004). The Xinglonggou Formation consists of sandstones at the base and high-Mg adakite, andesite and dacite in the upper unit (Gao and others, 2004; Yan and others, 2006). Two sandstone samples XL130 and XL131 were taken from the base of the Xinglonggou Formation (fig. 2). They consist of 70 percent plagioclase, 15 percent quartz and 15 percent amphibole. Majority of the amphibole show the characteristics of alteration. The existence of amphibole and the high content plagioclase imply that they were derived from a near-by source. Zircons are typically prismatic or rounded to subhedral and lack of crack (fig. 3), which also suggests first cycle materials with short-distance of transportation.

ANALYTICAL METHODS

Samples of >10 kg were crushed and powdered. Zircons were separated by heavy-liquid and magnetic methods and then purified by hand picking under a binocular microscope. >2000 zircon grains were separated, from which >200 were selected and mounted on a double-sided tape, cast in epoxy resin, and polished to expose surfaces suitable for laser ablation inductively coupled plasma mass spectrometer (LA-ICP-MS) analysis. The surface of the grain mounts was acid-washed in dilute HNO₃ and pure ethanol to suppress lead contamination. As we are concerned with crustal growth related to magmatism, igneous zircons showing cathodoluminescence (CL) images of oscillatory zoning (fig. 3) were selected for age dating and Hf isotopic analysis. Metamorphic zircons, if any, were not considered. In addition, igneous zircon domains selected are free of cracks and inclusions, as guided by transmitted and reflected light images. Otherwise, zircons for analysis were selected randomly.

CL Imaging

Cathodoluminescence images of zircons were carried out using Quanta 400FEG high resolution emission field environmental scanning electron microscope connected with an Oxford INCA350 energy dispersive system and a Gatan Mono CL3+ CL system at the State Key Laboratory of Continental Dynamics, Northwest University. The imaging conditions were 10 kv with a spot size of 6.7 nm and a working distance of 8.4 mm. The CL images were used to demonstrate the internal textures of zircons and to select optimum spot locations for U-Pb dating.

U-Pb Dating

Zircons were dated on an excimer (193 nm wave length) laser ablation inductively coupled plasma mass spectrometer (LA-ICP-MS) at the State Key Laboratory of Continental Dynamics, Northwest University. The ICP-MS used is Agilent 7500a. The GeoLas 200M laser-ablation system (MicroLas, Göttingen, Germany) was used for the laser ablation experiments. Helium was used as carrier gas. The used spot size and laser frequency were 30 μ m and 10 Hz, respectively. The data acquisition mode was peak jumping (20 ms per isotope each cycle). Raw count rates were measured for ²⁹Si, ²⁰⁴Pb, ²⁰⁶Pb, ²⁰⁷Pb, ²⁰⁸Pb, ²³²Th and ²³⁸U. U, Th and Pb concentrations were calibrated by using ²⁹Si as an internal standard and NIST SRM 610 as the reference standard. Each analysis consists of 30s gas blank and 40s signal acquisition. High-purity argon was used in combination with a home-made helium filtration column composed of a 10 L 13 \times molecular sieve. This column has filtering performance similar to charcoal filters (Hirata and Nesbitt, 1995; Hirata and others, 2005) and gold traps (Storey and others, 2006). The gas purification reduces the gas backgrounds of ²⁰²Hg from >800 counts per second (cps) to <200 cps and those of ²⁰⁸Pb from >400 cps to <100 cps. These

Fig. 2. Mesozoic stratigraphic column of western Liaoning (modified after Chen and others, 1997). Our samples are from the bottom of the Xinglonggou Formation at the south of Beipiao as represented by the star.

backgrounds were measured by ion counters (MC-ICPMS); they correspond to 0.05 and 0.1 parts per trillion (ppt) for ^{202}Hg and ^{208}Pb , respectively (Yuan and others, 2008). $^{207}\text{Pb}/^{206}\text{Pb}$, $^{206}\text{Pb}/^{238}\text{U}$, $^{207}\text{Pb}/^{235}\text{U}$ and $^{208}\text{Pb}/^{232}\text{Th}$ ratios, calculated using

Fig. 3. Cathodoluminescence (CL) images of representative detrital zircons from the Xinglonggou Formation. For XL130, small and large circles indicate locations for U-Pb dating by LA-ICP-MS and *in-situ* Hf isotope analysis, respectively. Circles for XL131 indicate locations for simultaneous U-Pb and Hf isotope analysis. Numbers denote $^{207}\text{Pb}/^{206}\text{Pb}$ ages for zircons ≥ 1.0 Ga and $^{206}\text{Pb}/^{238}\text{U}$ ages for zircons < 1.0 Ga.

GLITTER 4.0 (Macquarie University), were corrected for both instrumental mass bias and depth-dependent elemental and isotopic fractionation using Harvard zircon 91500 as external standard. In data reduction, signals were selected to include the part as smooth and wide as possible with similar $^{206}\text{Pb}/^{238}\text{U}$ and $^{207}\text{Pb}/^{235}\text{U}$ ratios and signal spikes were eliminated. The ages were calculated using ISOPLOT 3 (Ludwig, 2003). Our measurements of GJ-1 (table 1) as an unknown yielded weighted $^{206}\text{Pb}/^{238}\text{U}$ ages of 603.2 ± 1.0 Ma (2σ , MSWD=0.03, $n=18$) (fig. 4), which is in good agreement with the apparent ID-TIMS $^{206}\text{Pb}/^{238}\text{U}$ ages of 598.5 to 602.7 Ma (Jackson and others, 2004). Analytical details for age and trace and rare earth element determinations of zircons are reported in Yuan and others (2004). Common Pb corrections were made following the method of Andersen (2002). Because measured ^{204}Pb usually accounts for < 0.3 percent of the total Pb, the correction is insignificant in most cases.

As shown by Vermeesch (2004), for provenance studies, a minimum of 117 detrital zircon grains have to be dated for a single sample in order to yield statistically significant results. A total of 121 zircons were dated for XL130 and 125 zircons for XL131.

TABLE 1
U-Pb isotopic data of zircon standard Gf-1

Analysis No.	Pb (ppm)	Th (ppm)	U (ppm)	isotopic ratios				Age (Ma)

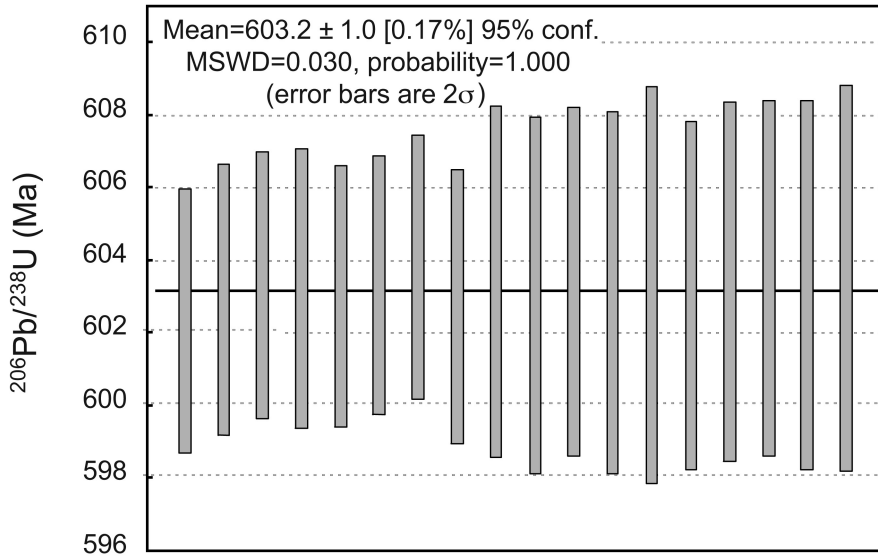

Fig. 4. Weighed mean age for zircon standard GJ-1.

Lu-Hf Isotope Analysis

Hf isotope analysis was done on a Nu Plasma HR MC-ICP-MS (Nu Instruments Ltd., UK), coupled to a GeoLas 2005 excimer ArF laser-ablation system hosted in the State Key Laboratory of Continental Dynamics, Northwest University. The energy density applied was 15–20 J/cm² and a spot size of 44 μm was used. Raw count rates for isotopes 171–177, 179, 180 and 182 were measured during a single data acquisition. Helium was also used as carrier gas. The sensitivity in laser ablation mode is 7–8 V per 1 percent of hafnium at 44 μm.

Isobaric interference corrections for ¹⁷⁶Lu and ¹⁷⁶Yb on ¹⁷⁶Hf must be determined precisely. The interference of ¹⁷⁶Lu on ¹⁷⁶Hf was corrected by measuring the intensity of ¹⁷⁵Lu and using the ¹⁷⁶Lu/¹⁷⁵Lu ratio of 0.02669 (De Bièvre and Taylor, 1993) to correct the measured ¹⁷⁶Hf/¹⁷⁷Hf ratios. Similarly, the interference of ¹⁷⁶Yb on ¹⁷⁶Hf was corrected by measuring the interference-free ¹⁷²Yb isotope and using the recommended ¹⁷⁶Yb/¹⁷²Yb ratio of 0.5886 (Chu and others, 2002) to calculate ¹⁷⁶Hf/¹⁷⁷Hf ratios. In doing so, a mean ¹⁷³Yb/¹⁷¹Yb ratio for the analyzed spot itself was automatically used in the same run to calculate a mean β_{Yb} value (Iizuka and Hirata, 2005), and then the ¹⁷⁶Yb signal intensity was calculated from the ¹⁷³Yb signal intensity and the mean β_{Yb} value.

The Hf isotopes were measured in two modes. For XL130, the analysis was done on the same spots or the same age domains for age determinations, as guided by CL images. For XL131, we used our developed technique of simultaneous determinations of U-Pb ages, Hf isotopes and trace element compositions of zircon by combining excimer laser ablation quadrupole and multiple collector ICP-MS (Yuan and others, 2008). This allows simultaneous collections of data on U-Pb age, Hf isotope and trace element composition of the same aerosol from the same spot of zircon. The similar Hf isotopic compositions obtained by the two modes of Hf analysis indicate that both modes of Hf analysis work and age zoning is not a problem for our zircons, which mostly do not show age zoning (fig. 3). Our measured values of three well-characterized zircon standards (91500, GJ-1 and MON-1) agree with the recom-

mended values to within 2σ (table 2). Detailed description of the technique and analyses of the six standard zircons (91500, Temora-2, GJ-1, Mud Tank, BR266 and Monastery) were reported in Yuan and others (2008).

The initial $^{176}\text{Hf}/^{177}\text{Hf}$ ratios were calculated with reference to the chondritic reservoir (CHUR) at the time of zircon growth from magmas. The decay constant for ^{176}Lu and the chondritic ratios of $^{176}\text{Hf}/^{177}\text{Hf}$ and $^{176}\text{Lu}/^{177}\text{Hf}$ used in calculations are $1.867 \times 10^{-11} \text{ yr}^{-1}$ (Scherer and others, 2001) and 0.282772 and 0.0332 (Bichert-Toft and Albarède, 1997), respectively. The two-stage continental model age ($T_{\text{DM}2}$) was calculated by projecting the initial $^{176}\text{Hf}/^{177}\text{Hf}$ of zircon back to the depleted mantle growth curve using $^{176}\text{Lu}/^{177}\text{Hf} = 0.0093$ for the upper continental crust (Vervoort and Patchett, 1996).

RESULTS

A total of 246 detrital zircons were dated, of which 180 are concordant with concordance within 90 to 110 percent. 149 concordant zircons were selected for Hf isotope analysis. Tables 3 and 4 give U-Pb and Hf data for the concordant zircons, respectively. Zircons are typically prismatic or rounded to subhedral. They are characterized by oscillatory zoning (fig. 3) and have Th/U ratios of >0.5 (fig. 5). These features indicate a magmatic origin and suggest first cycle materials with short-distance of transportation, which is supported by the presence of amphibole in the sandstones. The following discussion is confined to the concordant zircons. We use $^{207}\text{Pb}/^{206}\text{Pb}$ ages for zircons of age ≥ 1.0 Ga and $^{206}\text{Pb}/^{238}\text{U}$ ages for zircons of age < 1.0 Ga.

U-Pb Ages

The two samples show similar bimodal age groups. 121 zircon grains were analyzed and 77 concordant ages were obtained on XL130. The concordant zircons show two major age populations: 255 to 220 Ma and 2600 to 2400 Ma (figs. 6 and 7). The obtained youngest age is 215 ± 2 Ma (Spot XL130-068) and the oldest age is 2584 ± 5 Ma (Spot XL130-100).

Conc. (%) is percentage concordance defined as $[(^{206}\text{Pb}/^{238}\text{U})\text{age}/(^{207}\text{Pb}/^{206}\text{Pb})\text{age}] \times 100$.

The initial $^{176}\text{Hf}/^{177}\text{Hf}$ ratios were calculated with reference to the chondritic reservoir (CHUR) at the time of zircon growth from magmas. $\varepsilon_{\text{Hf}}(t)$ values are defined to denote a 0.1 per mil difference between the sample and the chondritic reservoir at the time of magma crystallization. The decay constant for ^{176}Lu and the chondritic ratios of $^{176}\text{Hf}/^{177}\text{Hf}$ and $^{176}\text{Lu}/^{177}\text{Hf}$ used in calculations are $1.867 \times 10^{-11} \text{ yr}^{-1}$ (Scherer and others, 2001) and 0.282772 and 0.0332 (Bichert-Toft and Albarède, 1997), respectively. A two-stage continental model age (T_{DM2}) was calculated by projecting the initial $^{176}\text{Hf}/^{177}\text{Hf}$ of zircon back to the depleted mantle growth curve using $^{176}\text{Lu}/^{177}\text{Hf} = 0.0093$ for the upper continental crust (Vervoort and Patchett, 1996).

Fig. 5. Plots of Th/U ratios versus U-Pb ages of concordant detrital zircons.

125 zircon grains were analyzed and 103 concordant ages were obtained on XL131. The concordant zircons show similar two major age populations: 260 to 220 Ma and ca. 2400 Ma (figs. 6 and 7). Only two grains give the age of ~ 1.8 Ga. Two grains yield the identical youngest age 208 Ma (Spot XL130-032 and XL130-071) and the oldest age is 2446 ± 67 Ma (Spot XL130-098).

Hf Isotopes

149 representative concordant grains out of the dated 246 zircons were analyzed for the Hf isotopes (table 4). As shown in figure 8, the $\epsilon_{\text{Hf}}(t)$ values exhibit distinctive characteristics for different U-Pb age groups. Majority of the 2.6 to 2.4 Ga zircons have positive $\epsilon_{\text{Hf}}(t)$ up to the depleted mantle (DM) value and crustal model ages of 2.8 to 2.5 Ga. The 3 grains with U-Pb age of 1.9 to 1.6 Ga have $\epsilon_{\text{Hf}}(t)$ values of -0.8 to -17.3 and crustal model ages of 3.0 to 2.4 Ga. However, $\epsilon_{\text{Hf}}(t)$ values of the 260 to 220 Ma zircons range widely from -15.4 to 13.3 and 127 zircons of them have positive $\epsilon_{\text{Hf}}(t)$ values although 22 grains have the negative values. Again, the high values almost reach the depleted mantle value (fig. 8) and suggest juvenile crustal additions. The 260 to 220 Ma zircons have crustal model ages of 1882 to 372 Ma.

DISCUSSION

Source of Sandstones

As shown in figure 5, majority of the zircons have $\text{Th}/\text{U} > 0.50$ characteristic of an igneous origin (Hanchar and Hoskin, 2003). Typical metamorphic Th/U ratios (< 0.10) occur only for one zircon (XL130-57). Except for XL130-57 ($\text{Th}/\text{U} = 0.02$), all

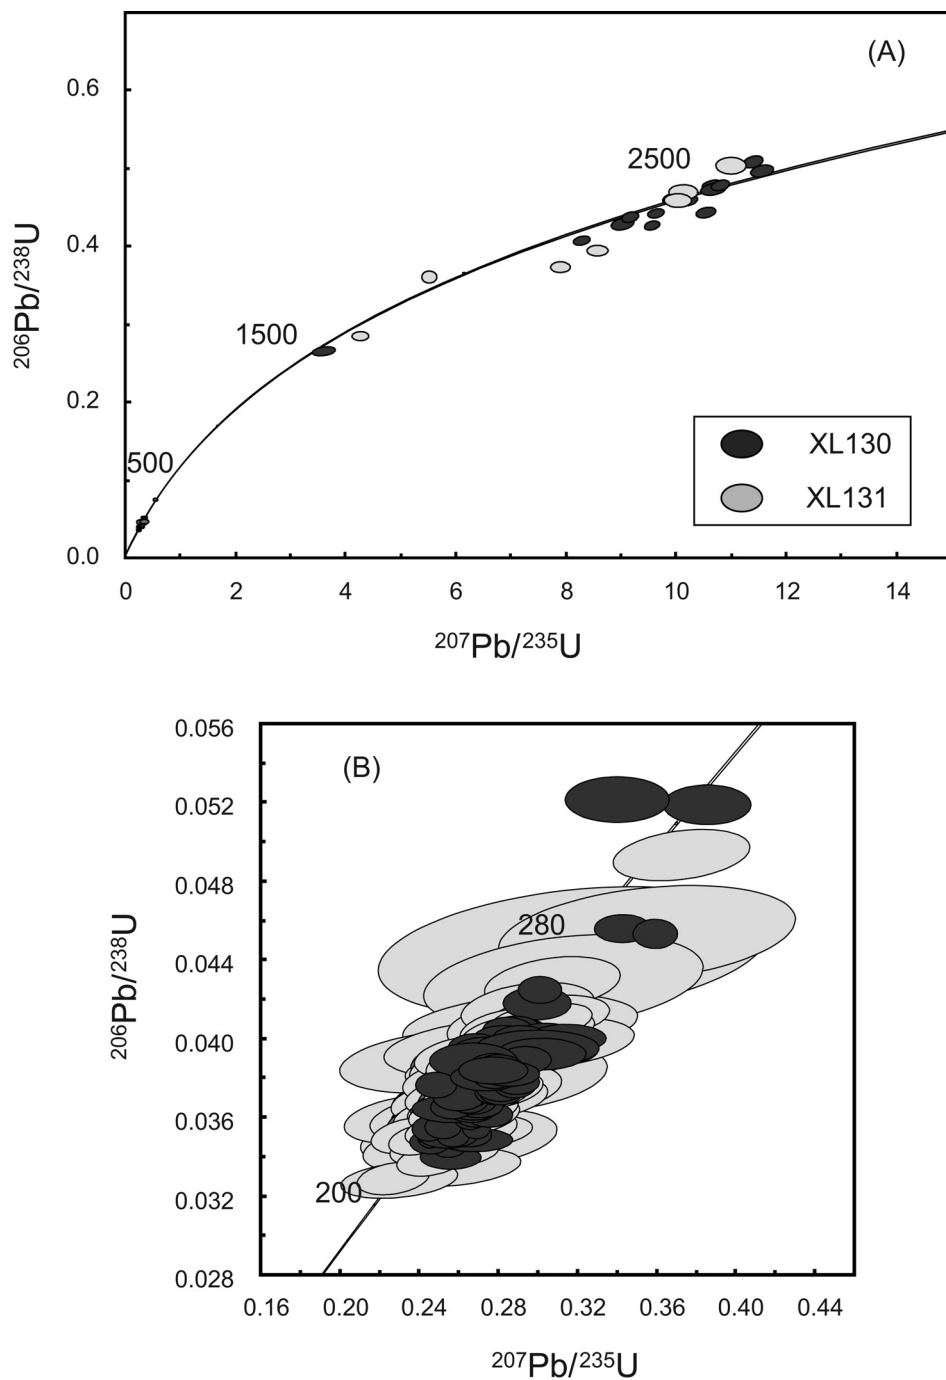

Fig. 6. U-Pb concordia ages of all detrital zircons (A) and Phanerozoic detrital zircons only (B) from the Xinglonggou Formation.

Fig. 7. Relative probability plots of U-Pb ages for all concordant detrital zircons (A), Phanerozoic concordant detrital zircons (B), and Precambrian concordant detrital zircons (C) from the Xinglonggou Formation.

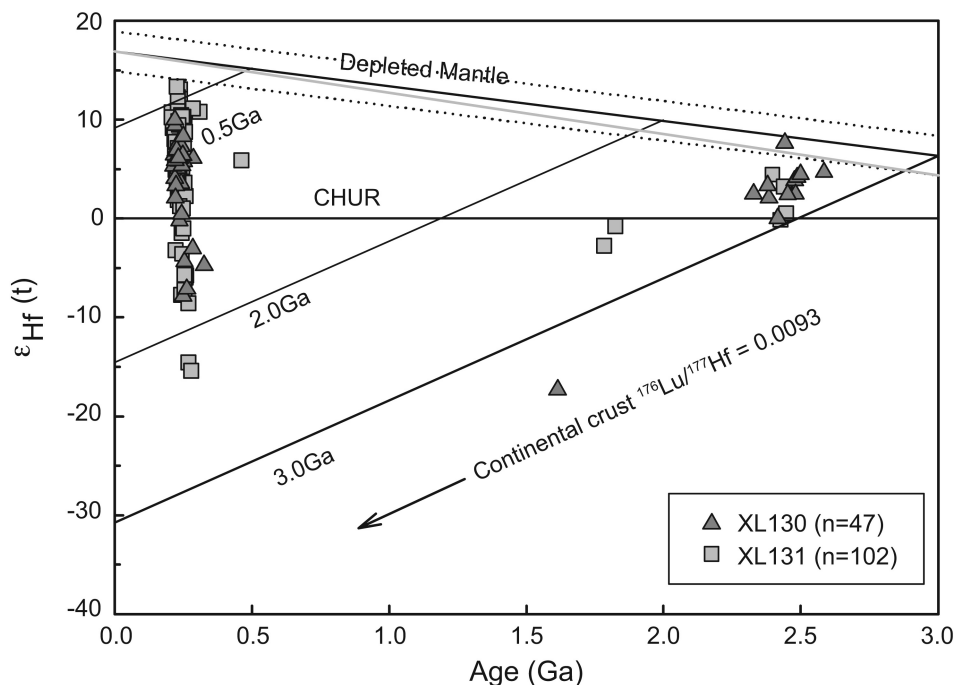

Fig. 8. U-Pb ages versus $\epsilon_{\text{Hf}}(t)$ value plots of concordant detrital zircons from the Xinglonggou Formation. The depleted mantle growth curve (black solid line) was calculated assuming a present-day $^{176}\text{Hf}/^{177}\text{Hf} = 0.28325$, $^{176}\text{Lu}/^{177}\text{Hf} = 0.0384$ (Griffin and others, 2002) and the dotted lines represent two ϵ_{Hf} units variation of the depleted mantle growth curve. The gray line represents depleted mantle growth curve based on zircon data (Pietranik and others, 2009).

the zircons show similar characteristics of “magmatic-like” zircon REE patterns with high positive Ce anomalies and steep increase from La to Lu (Pelletier and others, 2007). The results are consistent with the CL images predominated by oscillatory zoning typical of igneous origin (fig. 3).

As shown in figures 6 and 7, although the obtained zircon ages show a wide range from 2584 to 208 Ma, major age groups peak at 228 Ma and 2480 Ma (fig. 7A). They account for 87.2 percent and 11.2 percent of the total population, respectively. In addition, three grains range from 1.9 to 1.6 Ga. Only three grains give the age of 330 to 300 Ma. In detail, the 260 to 220 Ma zircons show a major peak at 232 Ma and 249 Ma (fig. 7B). The youngest U-Pb age (208 Ma), which can be used to define the maximum depositional age of sedimentary rocks (Nelson, 2001; Yang and others, 2006; Li and others, 2007; Kirkland and others, 2008; Liu and others, 2008), indicates a maximum depositional age of Late Triassic time for the Xinglonggou Formation.

Zircon ages of the Precambrian basements of the North China craton mainly range from 2.8 to 2.5 Ga with a peak at 2.5 Ga (Zhao and others, 2001; Gao and others, 2004). As described above, some of the 2.5 Ga zircons show positive $\epsilon_{\text{Hf}}(t)$ value high up to coeval depleted mantle values with Hf model age of 2.8 to 2.5 Ga, indicative of juvenile crustal additions. Similar Hf isotopic compositions of the ca. 2.5 Ga zircons investigated in this study with that from the North China Archean basements indicates a common source (Yang and others, 2005; Yang and others, 2009). In addition to the ca. 2.5 Ga zircons, 1.9 to 1.6 Ga zircons are also abundant in the North China craton (Zhao and others, 2001). The 1.9 to 1.6 Ga zircons have negative $\epsilon_{\text{Hf}}(t)$ values and

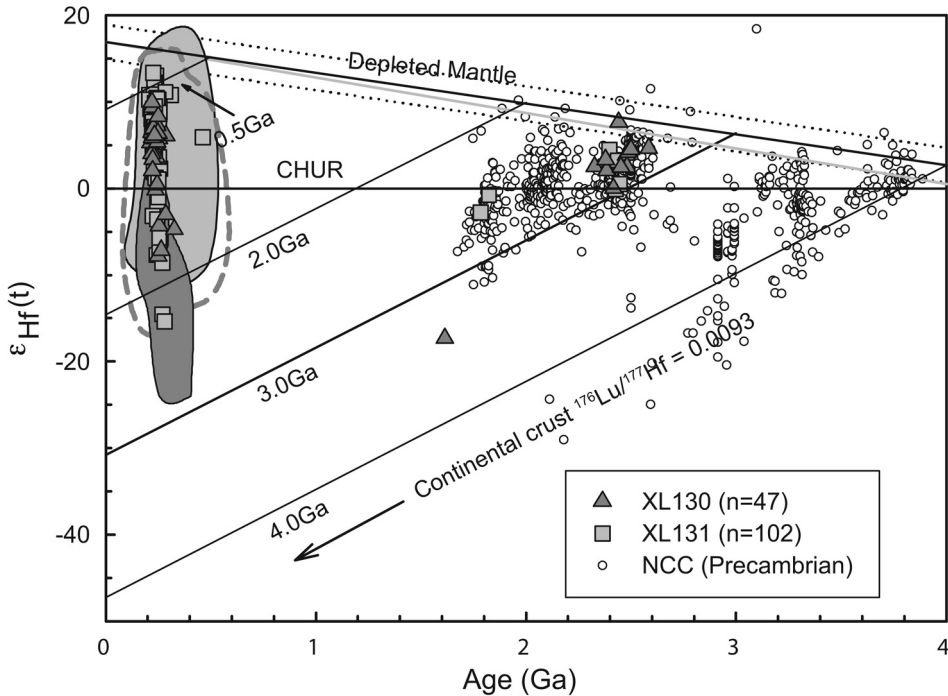

Fig. 9. Compilation of $\epsilon_{\text{Hf}}(t)$ vs. U-Pb ages of zircons from the North China craton and the eastern Central Asian Orogenic Belt. Depleted mantle growth lines are the same as in figure 8. The solid symbols represent the data from this study. Dashed line area represents detrital zircons from modern rivers covering the entire northeastern China, which comprises much of eastern Central Asian Orogenic Belt (Li, ms, 2010). Gray and dark gray areas indicate the Phanerozoic zircons from the eastern Central Asian Orogenic Belt (Zhou and others, 2005; Cheng and others, 2006; Chen and others, 2009) and the North China craton (Zheng and others, 2004; Wu and others, 2005b, 2008; Yang and others, 2006, 2007; Li and others, 2007; Tian and others, 2007; Wan and others, 2007; Zhang and others, 2007b; Luo and others, 2008), respectively.

their T_{DM2} ages vary from 3.0 to 2.4 Ga. These suggest remarkable reworking of pre-existing Archean crustal materials at 1.9 to 1.6 Ga. In contrast, rare Precambrian zircons were found in rocks of the eastern Central Asian Orogenic Belt (Yang and others, 2006; Chen and others, 2009). Previously identified Proterozoic metamorphic rocks are now considered to be Paleozoic in age (for example, Miao and others, 2004). The Jiamusi Massif is a Precambrian micro-continental block whose metamorphic age has been precisely dated at 500 Ma by SHRIMP zircon analyses (Wilde and others, 1997; 2000). These observations well document that the Precambrian zircons in the Xinglonggou sandstones were derived from the North China craton.

Phanerozoic igneous rocks are also present in the North China craton. Intrusive rocks, including diorite, granodiorite, monzogranite, syenogranite, A-type granite and syenite, and associated volcanic rocks, have zircon U-Pb ages of 390 to 111 Ma (for example, Luo and others, 2001, 2003; Miao and others, 2002, 2003; Gao and others, 2004; Han and others, 2004; Ma and others, 2004; Zhang and others, 2004, 2007a; 2007b, 2009a, 2009b; Wu and others, 2005a, 2005c, 2006; Yang and others, 2007, 2008). The whole-rock Nd isotopic data for the volcanic rocks of the North China craton show negative $\epsilon_{\text{Nd}}(t)$ values and older Nd model ages. Hf isotopes also give the same conclusion, Phanerozoic zircons from the North China craton have negative $\epsilon_{\text{Hf}}(t)$ values (fig. 9) and ancient Hf model ages (fig. 10) (Yang and others, 2006, 2007; Wu and others, 2007; Zhang and others, 2007b). According to the existing data, the

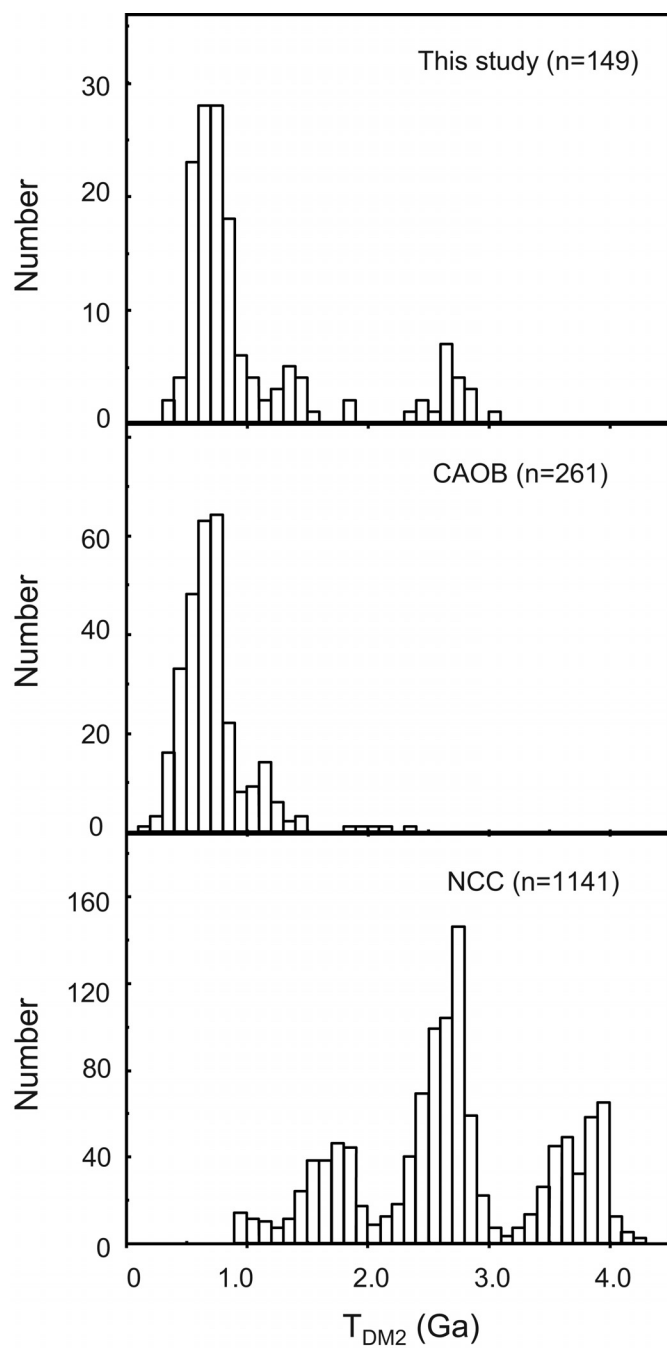

Fig. 10. Histogram of T_{DM2} ages of zircons from Xinglonggou Formation compared to igneous zircons from the North China craton (NCC) (Zheng and others, 2004; Wu and others, 2005b, 2008; Yang and others, 2006, 2007; Li and others, 2007; Tian and others, 2007; Wan and others, 2007; Zhang and others, 2007b; Luo and others, 2008) and the eastern Central Asian Orogenic Belt (CAOB) (Zhou and others, 2005; Cheng and others, 2006; Chen and others, 2009).

positive values in the North China craton were reported only by Yang and others (2006) for detrital zircons from western Beijing and Tian and others (2007) from northern Hebei, which have been interpreted as being derived from the Central Asian Orogenic Belt source or affected by subduction of the Paleo-Asian ocean.

In contrast, Phanerozoic zircons are distinct in the eastern Central Asian Orogenic Belt. The eastern segment of the Central Asian Orogenic Belt includes eastern and southern central Mongolia, northern Inner Mongolia of China, and northeastern China. The granites are dominant with rare mafic rocks. The ages of these rocks range from Late Paleozoic to Late Mesozoic (280-120 Ma) (Chen and others, 2000, 2009; Sun and others, 2000; Wu and others, 2000, 2002, 2003a; Jahn and others, 2001; Fan and others, 2003; Wang and others, 2004; Shi and others, 2004; Ge and others, 2005; Liu and others, 2005; Cheng and others, 2006; Jian and others, 2008; Miao and others, 2008; Zhang and others, 2008; Xu and others, 2009). Several plutons have been identified as early Paleozoic in age using the whole rock Rb-Sr method, which are considered to be unreliable. The granites of early Paleozoic age are not as widespread as previously thought. The well dated early Paleozoic plutons are distributed mainly along the northern margin of northeastern China (Ge and others, 2005; Zhou and others, 2005) and northern Inner Mongolia (Chen and others, 2000, 2009). Granitoids with ages mainly from 270 to 120 Ma are characterized by low initial Sr isotopic ratios and generally positive $\epsilon_{Nd}(t)$ values and young Nd model ages (for example, Shao and others, 1999; Chen and others, 2000, 2009; Jahn and others, 2000a, 2000b, 2004; Wu and others, 2000, 2002, 2003b, 2007; Miao and others, 2008; Zhang and others, 2008; Xu and others, 2009). Granitoids with negative $\epsilon_{Nd}(t)$ values also exist, but they occur in Precambrian blocks (for example, the Jiamusi Massif) and their isotopic compositions reflect contamination of the older crust in the magma generation. This characteristic also existed in other parts of the Central Asian Orogenic Belt (for example, Jahn, 2004; Kovalenko and others, 2004; Sun and others, 2008; Wang and others, 2009). Coupled with the whole-rock Nd isotopes, the Phanerozoic zircons from the eastern Central Asian Orogenic Belt have positive $\epsilon_{Hf}(t)$ values (fig. 9) and younger Hf model ages (fig. 10) (Zhou and others, 2005; Cheng and others, 2006; Yang and others, 2006; Chen and others, 2009). In summary, Phanerozoic zircons from the North China craton and the eastern Central Asian Orogenic Belt are distinct.

In this study, the Phanerozoic zircons mostly have the ages between 260 to 220 Ma, with only three zircons having ages of 330 to 300 Ma. As we discussed above, both the shape of the zircons and presence of amphibole in the sandstones support a near source for the Xinglonggou sandstones. This is reinforced by the restricted age populations of the zircon. The early Paleozoic ages in the eastern Central Asian Orogenic Belt were mainly distributed along the northern margin of northeastern China (Ge and others, 2005; Zhou and others, 2005) and northern Inner Mongolia (Chen and others, 2000, 2009), which lie in the northern Solonker suture and may have no or rare contribution to the Xinglonggou sandstones. A Late Carboniferous-Early Permian (ca. 330-298 Ma) Andean-style continental arc existed along the northern margin of the North China craton (Zhang and others, 2007a, 2009a). The 330 to 300 Ma zircons might have been derived from the Carboniferous magmatic arc along the northern margin of the North China craton with zircon U-Pb ages of 324 to 310 Ma (Zhang and others, 2004). However, the 260 to 220 Ma Xinglonggou zircons are characterized by positive $\epsilon_{Hf}(t)$ values and young Hf model ages, which are distinct from the North China craton zircons but similar to the eastern Central Asian Orogenic Belt zircons (figs. 9 and 10). Thus, the Xinglonggou zircons are mixtures of sources from the North China craton and eastern Central Asian Orogenic Belt with the predominance of the latter.

Triassic Crustal Growth and Tectonic Evolution

The Central Asian Orogenic Belt, which is the largest Phanerozoic accretionary orogen in the world (Sengör and others, 1993; Sengör and Natal'in, 1996), is critical to the study of continental crustal growth and geological history of central Asia. Phanerozoic crustal growth is evidenced by the emplacement of voluminous granitoids with low initial $^{87}\text{Sr}/^{86}\text{Sr}$, generally positive $\epsilon_{\text{Nd}}(t)$ values and young Nd model ages (Shao and others, 1999; Chen and others, 2000; Jahn and others, 2000, 2004; Wu and others, 2002, 2007). Such juvenile isotopic signatures are also exhibited by Phanerozoic granitoids in areas like New England, the Cordillera of North America (Samson and others, 1989; Pickett and Saleeby, 1999), Newfoundland Appalachians in Canada (Whalen and others, 1996) and Africa (Kinnaird and Bowden, 1987).

These studies are based on whole-rock analysis which may be compromised by mixing processes. *In-situ* analysis of Lu-Hf isotopic compositions of zircons provides less ambiguous timing of the crustal growth. Meanwhile, the Lu-Hf isotopic system of zircons is relatively immune to tectono-thermal events. As discussed above, 260 to 220 Ma Xinglonggou zircons show a wide range of $\epsilon_{\text{Hf}}(t)$ values from close to depleted mantle values to slightly negative values. These zircons can be interpreted by mixing of Permian-Triassic (260-220 Ma) new crustal additions with recycled Precambrian crust. The continuous $\epsilon_{\text{Hf}}(t)$ variation and the large number of zircons with positive $\epsilon_{\text{Hf}}(t)$ values suggest a possible magma mixing process with juvenile magma as the major component.

Two lines of evidence suggest that the Permian-Triassic (260-220 Ma) crustal growth documented by the Xinglonggou detrital zircons was widespread and significant for the entire eastern Central Asian Orogenic Belt. On one hand, 105 out of 167 concordant detrital zircons from modern rivers well covering the entire northeastern China, which comprises much of eastern Central Asian Orogenic Belt, also show positive ϵ_{Hf} up to the depleted mantle value for one of the major age groups at 270 to 210 Ma (see fig. 1A and fig. 9) (Li, ms, 2010). On the other hand, Permian-Triassic granitoids whose zircons show positive ϵ_{Hf} at the time of magma crystallization up to the depleted mantle value are voluminous in the eastern Central Asian Orogenic Belt (Cheng and others, 2006; Yang and others, 2006; Chen and others, 2009) (fig. 9).

As described above, previous studies of ophiolites and post-collision intrusive rocks suggest a west-east younging trend of a scissor-like closure of the Mongol-Okhotsk ocean (Donskaya and others, 2008). While as to the southern belt the closure occurred in late Carboniferous and post-collision intrusive rocks mainly produced at 300 to 280 Ma in the western Central Asian Orogenic Belt, the closure was completed in the Permian-Triassic and post-collision intrusive rocks range in age from 270 to 120 Ma in the eastern Central Asian Orogenic Belt. Therefore, the Permian-Triassic (260-220 Ma) crustal growth revealed by detrital zircons of this study cannot be applied to the western Central Asian Orogenic Belt, whose Phanerozoic crustal growth is expected around Late Carboniferous.

The continental crust can grow by lateral accretion of arc complexes in subduction zones and vertical addition of underplates in crust-mantle interface (Rudnick, 1990). As described above, the eastern Central Asian Orogenic Belt formed by final closure of the Paleo-Asian ocean, leading to formation of the Solonker suture and collision of the North China craton and the Mongolian Plate and Siberian craton. The Permian-Triassic (260-220 Ma) crustal growth may be related to the subduction and closure of the Paleo-Asian ocean. This is supported by the presence of Permian-Triassic ophiolites and volcanic and intrusive rocks. The Solonker ophiolite is considered to indicate the final collision between the North China craton and the Siberian craton. A single Rb-Sr isochron age of ~ 262 Ma (Wang and Liu, 1986) for the Balengshan ophiolite (~ 10 km northwest of Linxi) has been reported from the Solonker suture zone. 299 to 292 Ma ages also have been determined by dating ophiolitic gabbros

(Jian and others, 2008). In addition, basaltic andesite and rhyolite in Xilinhot in central Inner Mongolia (situated in the Solonker suture zone) yield weighted mean $^{206}\text{Pb}/^{238}\text{U}$ ages of 281 ± 3 Ma and 279 ± 3 Ma, respectively (Zhang and others, 2008). The Xilinhot mafic rocks show an asthenospheric mantle-like component ($^{87}\text{Sr}/^{86}\text{Sr}(t) \approx 0.704\text{--}0.705$, $\epsilon_{\text{Nd}}(t) \approx 6.87\text{--}7.90$, $(^{206}\text{Pb}/^{204}\text{Pb})_i = 18.08\text{--}18.18$) (Zhang and others, 2008). These characteristics are consistent with the age of the arc granitoids (~ 310 Ma), which constrain timing of the final collision along the Solonker suture zone to be no earlier than 310 Ma (Chen and others, 2000, 2009). Based on geochronological and geochemical data in Inner Mongolia and southern Mongolia, Jian and others (2010) suggest that the subduction and collision along the Solonker suture occurred between 300 to 270 Ma and slab break-off at 255 to 248 Ma. Li and others (2007) reported a zircon U-Pb age of 239 ± 5 Ma for a muscovite granite from Linxi (east Xilinhot). They considered the rock to have formed as a result of Solonker suturing. Wu and others (2007) also suggested that suturing of the Solonker suture zone occurred at ~ 250 Ma based on geochemical and geochronological data for the Hulan Group on the eastern extension of the Solonker suture, which is younger than timing reported by Jian and others (2010). It is possible that the closure is diachronous, which is consistent with the younging trend as indicated by post-collision volcanic rocks. Further work is needed. Permian-Triassic volcanic and intrusive rocks in the age range from 290 to 210 Ma are widespread and can be classified into two groups: Permian (290-250 Ma) (Sun and others, 2000; Shi and others, 2004) and Late Triassic (230-210 Ma) (Wu and others, 2000, 2002, 2004; Chen and others, 2000, 2009; Wang and others, 2004; Ge and others, 2005; Liu and others, 2005; Xu and others, 2009). As discussed above, if the subduction and closure of the Paleo-Asian ocean occurred between 300 to 250 Ma according to previous studies, the 290 to 250 Ma and 230 to 210 Ma volcanic and intrusive rocks may represent lateral accretion of arc complexes in subduction zone and vertical addition of underplates in post-collision environment, respectively. They show typical characteristics of the Central Asian Orogenic Belt with slightly negative to positive $\epsilon_{\text{Nd}}(t)$ values (-2 to 5.60) and young Nd model age (1000-500 Ma) except for the granites in the Jiamusi Massif with negative $\epsilon_{\text{Nd}}(t)$ (-6.84 to -7.36) and relatively older model ages (~ 1600 Ma). These indicate the involvement of the Precambrian crust. The Xinglonggou Formation in this study represents the first sedimentation after the final collision of the Siberian Plate with the North China craton. The closure of the Paleo-Asian ocean led to mixed sources of the North China craton and the eastern Central Asian Orogenic Belt in Xinglonggou sandstones. 260 to 220 Ma Xinglonggou zircons can be interpreted by mixing of Permian-Triassic (260-220 Ma) new crustal additions with Precambrian crust. The subduction and closure of the Paleo-Asian ocean may have been responsible for this crustal growth.

Although the timing and mechanism of the amalgamation between the North China and Siberian Plate is controversial, many workers favor the Late Permian to early Triassic (ca. 300-230 Ma) amalgamation along the Solonker suture zone (Zhang and others, 1984; Wang and Liu, 1986; Wang and Mo, 1995; Yin and Nie, 1996; Davis and others, 2001; Xiao and others, 2003; Yang and others, 2006; Lin and others, 2008; Jian and others, 2010). Yang and others (2006) studied detrital zircons from Paleozoic to Late Mesozoic (304-143 Ma) strata in the Xishan area near Beijing. Their results show a significant change in source provenance in Late Triassic to Late Jurassic (205-158 Ma) sandstones, which contain a group of Phanerozoic zircons with positive $\epsilon_{\text{Hf}}(t)$ values, distinct from known igneous zircons in the North China craton. They suggest a source from the eastern Central Asian Orogenic Belt, resulting from the exhumation and denudation of rocks due to uplift of the eastern Central Asian Orogenic Belt. Together with these results, our study supports closure of the eastern Solonker suture zone at the

end-Permian (~250 Ma). Since the Phanerozoic zircons from the North China craton are characterized by negative $\epsilon_{\text{Hf}}(t)$ values (Yang and others, 2006), the two youngest zircons with positive $\epsilon_{\text{Hf}}(t)$ values from the Xinglonggou sandstones constrain uplift of the eastern Central Asian Orogenic Belt to be no older than 208 Ma. This is also supported by an east-west-trending belt with numerous granitoid plutons ranging in age from 285 to 217 Ma along the northern margin of the North China craton (Ma and others, 2004; Zhang and others, 2004), which are considered to have resulted from collision between the North China craton and the Mongolian Plate (Wang and Liu, 1986; Wang and Mo, 1995).

As stated above, combination of Lu-Hf isotope and U-Pb age of detrital zircons from the Xinglonggou Formation revealed two episodes of crustal growth, one at Archean (ca. 2.5 Ga) in agreement with the North China craton and the other at 260 to 220 Ma related to the eastern Central Asian Orogenic Belt. As to the Archean crustal growth, it is consistent with the recent research on detrital zircons from modern rivers drained within the North China craton (Yang and others, 2009). In addition, the Archean peak agrees well with the worldwide compilations (for example, Pietranik and others, 2008; Condie and others, 2009). The Permian-Triassic (260-220 Ma) crustal growth is considered to be related to collision between the North China craton and the Mongolian Plate along the eastern Solonker suture, which records the termination of the Central Asian Orogenic Belt. The Solonker suture is 700 km long and 60 km wide and extends from Solonker via Sonid Yuqi to Linxi in Inner Mongolia and further west and northeast (Xiao and others, 2003), which represents a large area of Permian-Triassic (260-220 Ma) crustal growth. However, worldwide compilations do not suggest significant crustal growth after 450 Ma (Condie, 1998, 2000; Condie and others, 2009). Although there are cases of classic orogenic belts considered to be significant Phanerozoic crustal growth based on positive $\epsilon_{\text{Nd}}(t)$ of granitoids just as in Central Asian Orogenic Belt, *in-situ* determinations of U-Pb ages, Hf and oxygen isotopes of detrital zircons from the Lachlan Fold Belt of southeastern Australia reveal no Phanerozoic zircons having a Hf isotopic composition that approaches that of the depleted mantle at time of crystallization, which means they were derived by re-melting, rather than juvenile, crustal rocks (Kemp and others, 2006; Hawkesworth and Kemp, 2006a, 2006b). However, the analysis of detrital zircons in this study indeed reveals Permian-Triassic (260-220 Ma) crustal growth with $\epsilon_{\text{Hf}}(t)$ close to depleted mantle values. This implies extensive juvenile crustal additions during this period. Although the amount and rate of the crustal growth can not be established according to our data, the Permian-Triassic (260-220 Ma) crustal growth is significant. The Triassic crustal growth has also been reported in the Canadian Cordillera deduced from geochemical characteristics of Late-Paleozoic and Triassic mantle-derived magma (Lapierre and others, 2003). Our study provides evidence for significant Permian-Triassic (260-220 Ma) crustal growth in the eastern Central Asian Orogenic Belt.

Why did such a large area of Permian-Triassic (260-220 Ma) crustal growth occur in the Central Asian Orogenic Belt? Previous studies suggest the relationship between supercontinent assembly and crustal growth (for example, Condie, 1998, 2000), and the Permian-Triassic corresponds to the assembly of Pangaea, but whether there is any relationship between them needs full discussion of supercontinent reconstruction, which is beyond the scope of this paper. If this is the result of assembly of Pangaea, why Permian-Triassic crustal growth is rare in other areas? If this is a particular event in the eastern Central Asian Orogenic Belt, is there any relationship between the growth and Mesozoic reactivation of the North China craton? All these need further studies.

CONCLUSIONS

In situ U-Pb ages and Hf isotopic data from detrital zircons in the Xinglonggou Formation, western Liaoning, provide important constraint on the source provenance

and tectonic evolution of the eastern Central Asian Orogenic Belt. Zircons from the Xinglonggou sandstones are characterized by two major groups of U-Pb ages (2.6-2.4 Ga and 260-220 Ma) except for three grains (1.9-1.6 Ga). Hf isotopic compositions show juvenile crustal additions at 2.6 to 2.4 Ga and 260 to 220 Ma, while ancient crustal reworking occurred at 1.9 to 1.6 Ga.

Mixing of detritus from both the North China craton and the eastern Central Asian Orogenic Belt suggests that end-Permian (~250 Ma) closure of the Paleo-Asian ocean and collision between the North China craton and the Siberian Plate along the eastern Solonker zone. The youngest zircons constrain uplift of the eastern Central Asian Orogenic Belt to be no older than 208 Ma. Thus, the Permian-Triassic (260-220 Ma) crustal growth is related to the subduction of the Paleo-Asian ocean Plate. The analysis of detrital zircons in this study reveal significant Permian-Triassic (260-220 Ma) crustal growth with $\epsilon_{\text{Hf}}(t)$ close to depleted mantle values in the eastern Central Asian Orogenic Belt.

ACKNOWLEDGMENTS

This study is jointly supported by the MOST special funds from the State Key Laboratory of Continental Dynamics and the State Key Laboratory of Geological Processes and Mineral Resources, the National Nature Science Foundation of China (Grants 40973020, 40821061, 90714010 and 40673019), and the Ministry of Education of China (B07039). We thank J. J. Veevers and two anonymous reviewers for their helpful comments.
